(Dated: January 22, 2014)

Superconducting circuits and microwave signals are good candidates to realize quantum networks, which are the backbone of quantum computers. We have realized a universal quantum node based on a 3D microwave superconducting cavity parametrically coupled to a transmission line by a Josephson ring modulator. We first demonstrate the time-controlled capture, storage and retrieval of an optimally shaped propagating microwave field, with an efficiency as high as 80%. We then demonstrate a second essential ability, which is the timed-controlled generation of an entangled state distributed between the node and a microwave channel.

Microwave signals are a promising resource for quantum information processing. Coupled to various quantum systems [1–4] they could realize quantum networks, in which entangled information is processed by quantum nodes and distributed through photonic channels [5, 6]. The quantum nodes should generate and distribute microwave entangled fields while controlling their emission and reception in time. Superconducting circuits are able to generate entanglement [7–10] and quantum memories provide control in time as demonstrated in emerging implementations in the microwave domain using spin ensembles [11–13], superconducting circuits [14, 15] or mechanical resonators [16, 17]. Here, we present a superconducting device both able to store and generate entangled microwave radiations shared between a memory and a propagating mode. It is based on the Josephson ring modulator [18, 19] that enables to switch dynamically on or off the coupling between a low-loss cavity and a transmission line by frequency conversion. We demonstrate the time-controlled capture, storage and retrieval of a propagating coherent state in a long lived electromagnetic mode. Exploiting the versatility of this circuit, we then demonstrate the timed-controlled generation of an Einstein-Podolsky-Rosen (EPR) state distributed between the quantum memory and a propagating mode. These new capabilities pave the way for complex quantum communication and quantum computing protocols by means of photonic channels in the microwave domain.

The superconducting node is made of three components: a memory, a buffer and a parametric coupler linking them. The memory is the fundamental mode \( \hat{m} \) at frequency \( f_m = 7.80 \text{ GHz} \) of a low-loss 3D superconducting cavity cooled down to 40 mK (Fig. 1). The buffer is the fundamental mode \( \hat{a} \) at frequency \( f_a \) of an on-chip resonator and is the only component directly coupled to the network channels with propagating modes \( \hat{a}_{\text{in/out}} \). The large coupling rate \( \kappa_a = (20 \text{ ns})^{-1} \) between buffer and channel ensures fast communication compared to decoherence. The memory and buffer are parametrically coupled through a ring of four Josephson junctions pumped with a classical control field \( p \) at fre-
The device operates in two distinct ways depending on the pump frequency $f_p$. The magnetic flux through the ring allows to tune $f_p$ between 8.7 and 9.6 GHz. As described in previous works [20], the ring performs three-wave-mixing and $H_{mix} = \hbar \chi (\hat{a} + \hat{a}^\dagger)(\hat{m} + \hat{m}^\dagger)(p + p^*)$. The device can be operated in two distinct ways depending on the pump frequency. For $f_p = |f_a - f_m|$, the device operates as a converter [18, 21]. In the rotating wave approximation (RWA) and with $p > 0$ the term $H_{conv} = \hbar \chi p (\hat{a}^\dagger \hat{m} + \hat{m}^\dagger \hat{a})$ provides a tunable coupling rate $\chi p$ with frequency conversion between the buffer and memory modes. Conversely, for $f_p = f_a + f_m$, the RWA leads to the parametric down-conversion Hamiltonian $H_{pd} = \hbar \chi p (\hat{a}^\dagger \hat{m}) \hat{a}^\dagger \hat{m}^\dagger$. The device then operates as an entanglement generator [9]. Starting from the vacuum state, an EPR state is distributed between the propagating mode $\hat{a}_{out}$ and memory mode $\hat{m}$. These properties offer a striking resemblance with memories based on mechanical resonators whose input/output rates and frequencies are two to three orders of magnitude smaller [16, 17].

In order to demonstrate the performances of the memory, one can first capture and retrieve a propagating classical field. Depending on its temporal shape, the pump amplitude has to be shaped appropriately in order to maximize the capture efficiency [22]. In this experiment, we used the dual approach of optimizing the temporal shape of an incoming coherent state so that it is captured by a square pulse pump turning off at time $t = 0$ (Fig. 2a). The optimal shape corresponds almost to the time-reverse of a signal retrieved from an initially occupied memory [15, 23]. It depends on the input/output rate $\gamma_{io}$ as $\kappa_a(t) \propto \theta(\Delta t - \tau) \propto (\kappa_a - \gamma_{io})/2$. The first term ensures absorption without reflection, while the second term permits the complete transfer of the absorbed pulse from the buffer to the memory cavity. The amplitude of the pulse was chosen in order to maximize the input/output rate to $\gamma_{io}^0$. Indeed, for large enough pump powers such that $\chi p > \kappa_a/2$ the modes $\hat{a}$ and $\hat{m}$ hybridize and the input/output rate saturates to $|23\rangle \kappa_a^0 = \kappa_a (1 - \sqrt{1 - (2\kappa_a/\kappa_c)^2})/2 \approx (110 \text{ ns})^{-1}$. Note that it corresponds to the fully hybridized input/output rate $\kappa_a^0/2$ reduced by the antenna coupling rate $\kappa_c$, which is defined by the exit rate $\kappa_c \approx (50 \text{ ns})^{-1}$ of the 3D mode if the antennas are directly connected to a transmission line through $\Delta$ port (Fig. 1). It is worthwhile to note that, although the memory has a finite lifetime, the frequency conversion between modes $m$ and $a$ ensures that the input/output rate is exactly zero $\gamma_{io} = 0$ when the pump is turned off, leading to an infinite on/off ratio. Besides, the device being non-resonant with the conversion operating frequency $f_p = f_a - f_m \approx 1.5$ GHz, the transfer rate can be varied much faster than $\kappa_a$.

The amplitude $\langle \hat{a}_{out} \rangle$ of the mode coming back from the device is measured for several pump pulse sequences (Fig. 2b). In a first control measurement (top trace), the pump is kept turned off such that the measurement corresponds to the directly reflected incoming pulse. Note that there are about 10 photons on average in the incoming wavepacket. In the following measurements (traces below) the pump is turned on before time 0 and after time $\tau$ (Fig. 2a). Only 5% of the incoming pulse energy is reflected while it is sent at $t < 0$ indicating the efficient absorption of this pulse shape. When the pump is turned back on after a delay $\tau$, the device releases the captured state back in the transmission line as can be seen in Fig. 2b. Note that the chosen temporal shape of the incoming signal is indeed the time reverse of these pulses up to an amplitude rescaling, which corresponds to the efficiency of the memory. Calculating the memory efficiency $\eta$, which is the ratio between the retrieved pulse energy and the incoming pulse energy leads to an exponential decay as a function of delay time $\eta(t) = \eta_0 e^{-t/\tau_m}$ (Fig. 2c). The memory lifetime $\tau_m = 3.3 \text{ s}$ is much larger than $\gamma_{io}^{-1}$ but limited by unidentified losses in the 3D cavity coupled to the antennas. The much smaller decay rates achieved in similar 3D cavities [24] leave room for improvement in the future. Note that the anomaly.

![Figure 2: (a) Capture, store and release protocol. Pulse sequences for the pump field $p$ (green) at the difference frequency $f_p = f_a - f_m$, the input field $a_in$ and the resulting output field $a_out$ (orange). The temporal shape of the input field is chosen in order to optimize the capture efficiency. (b) Time traces of the amplitude of the output field down converted to 40MHz and averaged $6 \times 10^5$ times. The top trace is measured without pump and reveals the optimized input signal. The following traces correspond to the sequence of (a) with increasing delay $\tau$ between capture and retrieval from 0 $\mu$s to 8 $\mu$s. (c) Dots: retrieval efficiency $\eta$ as function of delay $\tau$. $\eta$ is defined as the ratio of the retrieved energy normalized to the input energy. Plain line: exponential decay $\eta_0 e^{-\tau/\tau_m}$ characterizing the memory lifetime. Best fit obtained for $\eta_0 = 80 \%$ and $\tau_m = 3.3 \mu$s.](image-url)
lously large efficiency at zero delay $\eta(0) > \eta_0 = 80\%$ can be explained by a still occupied buffer cavity at time $t = 0$. Besides the outgoing phase is identical to that of the incoming pulse, demonstrating that the memory preserves phase coherence. Finally, the number of operations that can be performed by the memory within its lifetime is limited by the time-bandwidth product $\gamma_{\text{io}}\tau_m = 30$. This combination of large memory efficiency and time-bandwidth product makes this device a state of the art quantum memory [25].

Promisingly, the device cannot only be used as a memory but also as an entanglement generator. In a second experiment, we demonstrate the generation of an EPR state distributed between the propagating mode $\hat{a}_{\text{out}}$ and the memory mode. Note that this experiment has been performed during another cooldown of the same device for which the memory lifetime was slightly degraded to $\tau_m = 2.3\ \mu$s. Starting from the vacuum state both in the memory and in the mode $\hat{a}_{\text{out}}$, a pulse at pump frequency $f_p = f_a + f_m = 17.28\ \text{GHz}$ produces a two-mode squeezed vacuum state $|S_q\rangle = e^{iH_{pd}\tau/k}|0\rangle_m|0\rangle_m = \cosh(r)^{-1}\sum \tanh(r)^n |n\rangle_m |n\rangle_m$ where the squeezing parameter $r$ increases with the pump pulse amplitude [9]. The entanglement between memory and propagating modes can be demonstrated by measuring the correlations between the fluctuations of their mode quadratures, and showing that there is more correlation than allowed by classical physics [7, 8, 10]. The quadratures of both modes can be measured using the same detector on line $a$ provided that the memorized field is released into the transmission line at a later time.

The pulse sequence used in the experiment (Fig. 3a) starts by a square pump pulse at $f_p = f_a + f_m = 17.28\ \text{GHz}$ during $500\ \text{ns}$ that generates an EPR state. While one part of the pair is stored in the memory, the other part propagates in the transmission line, is amplified by an amplifier, and then measured using the heterodyne detection setup. At the end of a sequence, the four mode quadratures $X_a$, $P_a$, $X_m$ and $P_m$ have been measured (defining $X_m \equiv (\hat{m} + \hat{m}^\dagger)/2$ and $P_m \equiv (\hat{m} - \hat{m}^\dagger)/2i$).

The correlations can be calibrated using the known variance of the single mode quadratures. Indeed, for mode $a$, the thermal state corresponds to amplified vacuum fluctuations with a power gain $\cosh(2r)$ resulting in a variance for both quadratures $\Delta X_a^2 = \Delta P_a^2 = \cosh(2r)/4$. Note that we assume that the field is in the vacuum at thermal equilibrium with the refrigerator temperature $45\ \text{mK} \ll kT/B \approx 0.4\ \text{K}$. The calibration then comes down to determining the gain $\cosh(2r)$ precisely. This can be done by storing a small coherent field (about 1 photon on average) in the memory and measuring the output amplitudes with and without applying the entangling $500\ \text{ns}$ pump pulse at $f_p = 17.28\ \text{GHz}$ before release [9]. The entangling pulse effectively amplifies the coherent field with an amplitude gain $\cosh(r)$ which is here found to be equal to 1.51.

One can then calculate the covariance matrix $\mathcal{V}$ of the two mode state (Fig. 3b), which fully characterizes the EPR state since it is Gaussian with zero mean [27]. The FPGA processes $4 \times 10^7$ pulse sequences in $5\ \text{minutes}$ so that $\mathcal{V}$ is calculated with minimal post-processing [8, 23, 28]. In a coordinate system where $x = \{X_a, P_a, X_m, P_m\}$, one defines $V_{ij} = 2\langle(x_i x_j + x_j x_i) - 2\langle x_i \rangle \langle x_j \rangle \rangle$. Physically, it is meaningful to decompose it in four $2 \times 2$ block matrices.

$$\mathcal{V} = \begin{pmatrix} \alpha & \chi^T \\ \chi & \mu \end{pmatrix}. \tag{1}$$

The diagonal blocks $\alpha$ and $\mu$ are the single-mode covariance matrices for $\hat{a}$ and $\hat{m}$ respectively. Since an EPR state is thermal when disregarding the other mode, there is no correlation between quadratures $X$ and $P$ for a single mode and the variances $\Delta X^2$ and $\Delta P^2$ are almost
Figure 4: Covariance matrix and entanglement as a function of the storage time \( \tau \). (a) Pulse sequence with tunable storage time \( \tau \). (b) Dots: diagonal terms of the covariance matrix \( \mathcal{V} \) giving the energy of each mode. Lines: average value (for \( \alpha \)) and exponential fit (for \( \beta \)). The decay rate of the terms in \( \beta \) gives the energy relaxation time \( T_1 = 2.3 \pm 0.1 \mu s \). (c) Dots: Off-diagonal amplitudes in \( \mathcal{V} \) representing the coherence between memory and propagating modes. Line: exponential fit, whose rate sets the decoherence time \( T_2 = 4.5 \pm 0.1 \mu s \). Correlations above the entanglement threshold (\( E_N = 0 \)) demonstrate entanglement between memory and propagating modes. (d) Dots: Logarithmic negativity \( E_N \) measuring the entanglement between modes. Line: prediction [23].

The experiment was repeated for various storage times \( \tau \) (Fig. 4a). The typical amplitude \( \sqrt{\text{det}[\mathbf{\overline{\mu}}]} \) of the memory mode terms in \( \mathcal{V} \) decrease exponentially with \( \tau \) (Fig. 4b) as expected from the experiment with coherent states in Fig. 2c. This leads to a relaxation time for the memory of \( T_1 = 2.3 \pm 0.1 \mu s \) in agreement with the memory lifetime \( \tau_m \) measured using coherent states in the same cool down of the device. The small variations in the amplitude of the propagating mode \( \sqrt{\text{det}[\mathbf{\overline{\mu}}]} \) with \( \tau \) give a sense of the measurement uncertainty (Fig. 4b). Interestingly, the two-mode correlations also decay exponentially (Fig. 4c). The corresponding characteristic time is the decoherence time \( T_2 \approx 4.5 \pm 0.1 \mu s \) of the memory. The fact that \( T_2 \approx 2T_1 \) demonstrates that energy relaxation dominates all decoherence mechanisms during the storage of a quantum state. The logarithmic negativity also decreases with \( \tau \) as shown in Fig. 4d.

In conclusion, we have realized quantum node based on an hybrid 2D/3D superconducting circuit. The efficient capture, storage and retrieval of a coherent state was demonstrated. Moreover, the device permits the generation and storage of entangled states distributed between the node and photonics channels. The versatility of the device paves the way for complex quantum communication protocols in the microwave domain such as continuous variable quantum teleportation. Besides, it provides a useful resource for 3D cavities where the on-demand extraction of a field quantum state was needed. This could be used to implement readout and feedback in cavity networks or even quantum computation with the memory field itself [29]. Finally, superconducting qubits can easily be embedded in this device, which could lead to protected quantum memories [4] and even protected quantum computing with microwave fields [29, 30].
